Unit #8: Shared-Memory Parallelism and Concurrency

CPSC 221: Algorithms and Data Structures

Will Evans and Jan Manuch

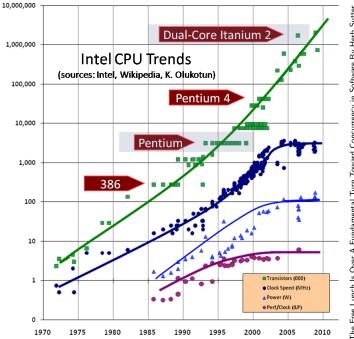

2016W1

Unit Outline

- History and Motivation
- Parallelism versus Concurrency
- Counting Matches in Parallel
- Divide and Conquer
- Reduce and Map
- Analyzing Parallel Programs
- Parallel Prefix Sum

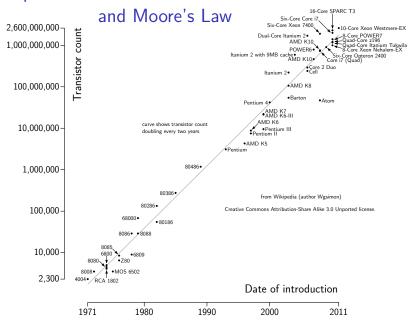

Learning Goals

- Distinguish between parallelism improving performance by exploiting multiple processors – and concurrency – managing simultaneous access to shared resources.
- ▶ Use the **fork/join** mechanism to create parallel programs.
- Represent a parallel program as a DAG.
- ▶ Define Work the time it takes one processor to complete a computation; Span the time it takes an infinite number of processors to complete a computation; Amdahl's Law the speedup obtainable by parallelizing as a function of the proportion of the computation that is parallelizable.
- ▶ Use Work, Span, and Amdahl's Law to analyze the possible speedup of a parallel version of a computation.
- ▶ Determine when and how to use parallel Map, Reduce, and Prefix Sum patterns.

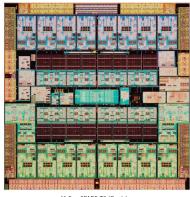

The Free Lunch Is Over A Fundamental Turn Toward Concurrency in Software By Herb Sutter

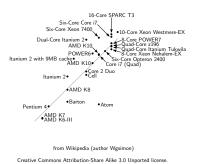

Microprocessor Transistor Counts 1971-2011

Microprocessor Transistor Counts 2000-2011

16-Core SPARC T3 (Oracle)

Parallelism versus Concurrency

Parallelism

Performing multiple steps at the same time. 16 chefs using 16 ovens.

Concurrency

Managing access by multiple agents to a shared resource. 16 chefs using 1 oven.

Who's doing the work?

Processor/Core Machine that executes instructions – one instruction at a time.

In reality, each core may execute (parts of) many instructions at the same time.

Process Executing instance of a program.

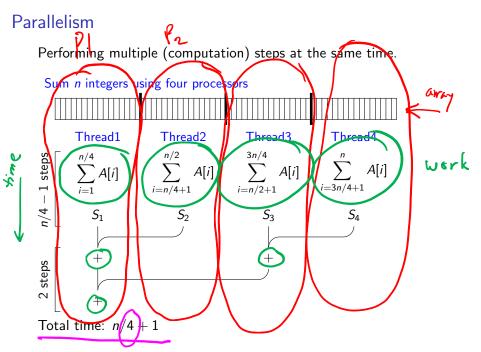

The operating system schedules when a process executes on a core.

Thread Light-weight process.

Each process may create many threads, but threads are still scheduled by the operating system.

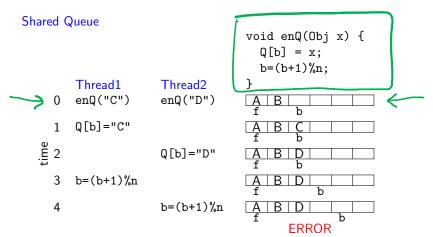

Task Light-weight thread. (in OpenMP 3.x)

A task may be scheduled for execution using a different mechanism than the operating system.

Concurrency

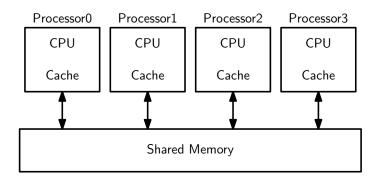

Managing access by multiple executing agents to a shared resource.

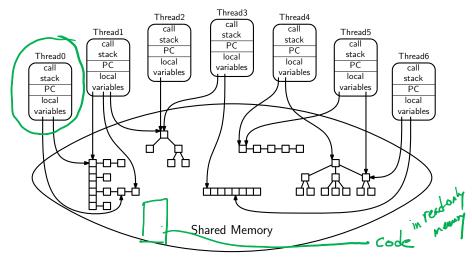

Models of Parallel Computation

- Shared Memory Agents read from and write to a common memory.
- Message Passing Agents explicitly send and receive data to/from other agents. (Distributed computing.)
 - Data flow Agents are nodes in a directed acyclic graph. Edges represent data that an agent needs as input (incoming) and produces as output (outgoing). When all input is available, the agent can produce output.
- Data parallelism Certain operations (e.g., sum) execute in parallel on collections (e.g., arrays) of data.

Shared Memory in Hardware

Shared Memory in Software

PC = program counter = address of currently executing instruction

Count Matches

How many times does the number 3 appear?

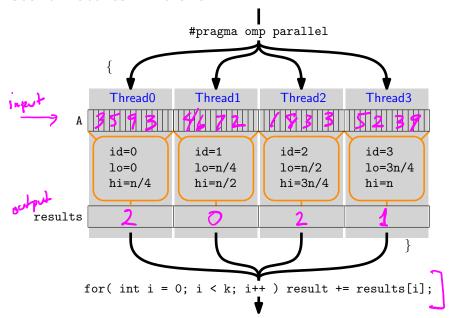

```
3 5 9 3 4 6 7 2 1 8 3 3 5 2 3 9
```

```
// Sequential version
int nMatches(int A[], int lo, int hi, int key) {
  int m = 0;
  for( int i=lo; i<hi; i++ )
    if( A[i] == key ) m++;
  return m;
}</pre>
```

```
gile per thread
 Count Matches in Parallel
number of melches
     #include "omp.h"
     int nmParallel(int A[], int n, int key) {
       int k = 4:
                            if(k > n) k = n:
      int results[k];
                           int nn = n/k:
       omp_set_num_threads(k);
       #pragma omp parallel .
         int id=omp_get_thread_num(), lo = id * nn, hi;
         if (id == k-1) hi = n; else hi = lo + nn;
        results[id] = nMatches(A, lo, hi, key);
       int result = 0;
       for( int i = 0; i < k; i++ ) result += results[i];</pre>
       return result;
```

k is the number of threads.

Count Matches in Parallel

How many agents (threads)?

Let n be the array size and k be the number of threads.

- 1. Divide array into k pieces.
- 2. Solve these pieces in parallel. Time $\Theta(n/k)$ using k processors
- 3. Combine by summing the results. Time $\Theta(k)$

Total time:
$$\Theta(n/k) + \Theta(k)$$
.

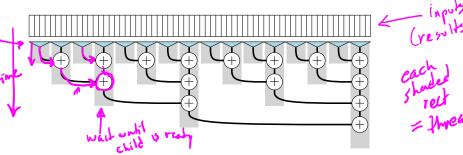

What's the best value of k? \sqrt{n}

Couldn't we do better if we had more processors? Combine is the bottleneck...

Combine in parallel

The process of producing a single answer¹ from a list is called **Reduce**.

Reduce using \oplus can be done in parallel, as shown, if

$$((a \oplus b) \oplus c) \oplus d = (a \oplus b) \oplus (c \oplus d)$$

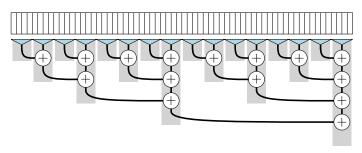

which is true for associative operations.

you + x min

¹A "single" answer may be a list or collection of values.

Combine in parallel

How do we create threads that know how to combine in parallel?

Does this look like anything we've seen before?

Combine in parallel

How do we create threads that know how to combine in parallel? MergeSort (left) Does this look like anything we've seen before? The "merge" part of Mergesort!

```
Count Matches with Divide and Conquer
Share parents "left" variable with child task
   int nmpDC(int A[], int lo, int hi, int key) {
     if( hi - lo <= CUTOFF ) return nMatches(A, lo, hi, key);
     int left, right;
   #pragma omp task untied shared(left)
     { left = mpDC(A, lo, (lo + hi)/2, key); }
                                                   execute on d
     right = nmpDC(A, (lo + hi)/2, hi, key);
                                                   thread different
                                                     from parent's
  #pragma omp taskwait
     return left + right;
   int nmpDivConq(int A[], int n, int key) {
                                                number of matches
     int result;
                                               in porallel Divide and
   #pragma omp parallel
   #pragma omp single
     { result = nmpDC(A, 0, n, key); }
     return result;
```

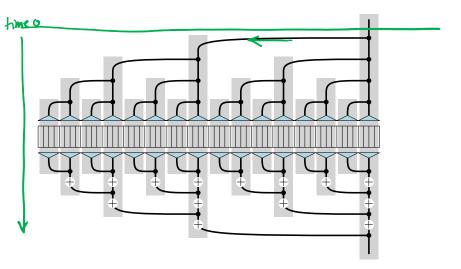

Efficiency Considerations

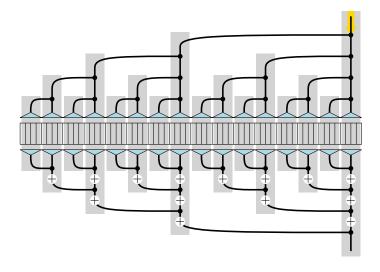

Why use tasks instead of threads?

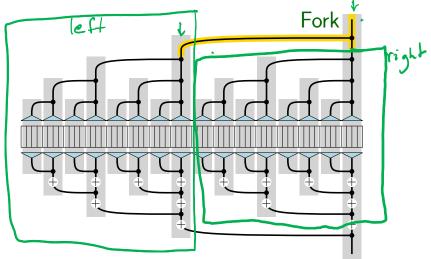

Creating and scheduling threads is more expensive.

Why use CUTOFF to switch to a sequential algorithm?

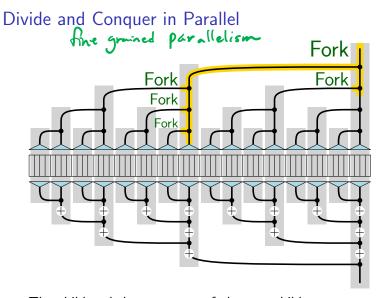

Creating and scheduling tasks is still somewhat expensive. We want to balance that expense with the amount of work we give the task.

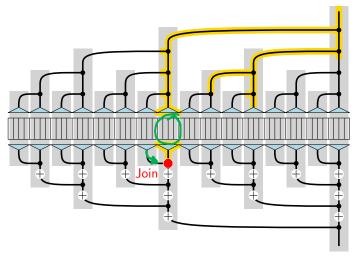

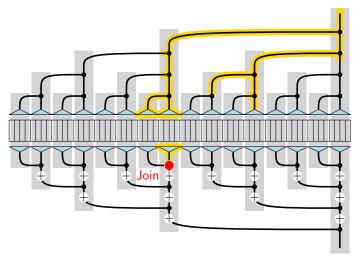

Fork Process creates (forks) a new child process. Both continue executing the same code but they have different IDs.

The child and the parent can fork more children.

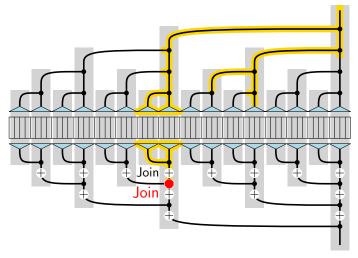

Join Process waits to recombine (join) with its child until the child reaches the same join point.

Still waiting... Why wait?

Join insures that the child is done before the parent uses its value.

After join the child process terminates and the parent continues.

Count Matches with Divide and Conquer

```
int nmpDC(int A[], int lo, int hi, int key) {
  if( hi - lo <= CUTOFF ) return nMatches(A, lo, hi, key);
  int left, right;
#pragma omp task untied shared(left) Fork
  { left = nmpDC(A, lo, (lo + hi)/2, key); }
  right = nmpDC(A, (lo + hi)/2, hi, key);
#pragma omp taskwait Join
  return left + right;
int nmpDivConq(int A[], int n, int key) {
  int result;
#pragma omp parallel
#pragma omp single
  { result = nmpDC(A, 0, n, key); }
  return result;
```

Efficiency with many processors

Let n be the array size and P the number of processors. Old Way

- 1. Divide array into *P* pieces.
- 2. Solve these pieces in parallel. Time $\Theta(n/P)$
- 3. Combine by summing the results. Time $\Theta(P)$

Total time: $\Theta(n/P) + \Theta(P)$

Suppose the number of processors, *P*, is infinite...

Divide and Conquer Way

- 1. Recursively divide array into CUTOFF-size pieces. Time $\Theta(\log n)$
- 2. Solve these pieces in parallel. Time $\Theta(\text{CUTOFF})$
- 3. Combine by summing the results. Time $\Theta(\log n)$

Total time $\Theta(\log n)$.

Is Counting Matches simply a Reduction?

```
FORALL x in A:
score = (if x == key then 1 else 0)
total += score
reduchon with += score
```

FORALL is short for "Do every iteration in parallel."

```
// OpenMP equivalent
#pragma omp parallel for reduction(+)total)
for (i=0; i < n; i++)
total += (A[i] == key) ? 1 : 0;</pre>
```

Map

A map operates on each element of a collection independently to create a new collection of the same size.

- No combining results
- Some hardware supports this directly

Counting matches is a Map (using equalsMap) followed by a Reduce (using +).

```
void equalsMap(int score[], int A[], int n, int key) {
  FORALL( i=0; i<n; ++i ) {
    score[i] = (A[i] == key) ? 1 : 0;
  }
}</pre>
```

Another Map Example: Vector Addition

```
\langle 1,2,3,4,5\rangle + \langle 2,5,3,3,1\rangle = \langle 3,7,6,7,6\rangle
```

```
void vectorAdd(int sum[], int u[], int v[], int n) {
   FORALL( i=0; i<n; ++i ) {
      sum[i] = u[i] + v[i];
   }
}</pre>
```

Parallel programming by Patterns

Map and Reduce are very common patterns in parallel programs.

Learn to recognize when an algorithm can be written in terms of Map and Reduce. They make parallel programming simple.

By the way... Google's MapReduce and the open-source Hadoop provide parallel Map and Reduce using clusters of computers.

- system distributes data and manages fault tolerance
- you provide Map and Reduce functions
- old functional programming ideas (map and fold) take over the world!

Map / Reduce Exercises

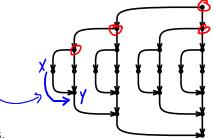

- 1. Find the ten largest numbers in an array.
- 2. Count the number of prime numbers in an array of positive integers.
- 3. Given a (small) pattern string and a (large) text string, find the first occurrence of the pattern in the text.

Modeling Parallel Programs as DAGs

Every parallel program can be modeled as a directed, acyclic graph (DAG).

Nodes represent a constant amount of sequential work.

Edges represent dependency: (x, y) means work x must complete before work y starts.

Runtime of Parallel Programs

Let $T_P(n)$ be the running time of a parallel program using P processors on an input of size n.

 $T_1(n)$ is called the **Work**

Work equals (some constant times) the number of nodes.

 $T_{\infty}(n)$ is called the **Span**

Span equals (some constant times) the number of nodes on the longest path.

For nmDivConq on input of size n (or $n \times \text{CUTOFF}$), the number of nodes is 3n-2 so $T_1(n) \in \Theta(n)$, and the longest path has $2 \lg n + 1$ nodes so $T_{\infty}(n) \in \Theta(\log n)$.

Runtime as a function of n and P

What is $T_P(n)$ in terms of n and P?

time to execute P processors.

- $T_P(n) \ge T_1(n)/P$ because otherwise we didn't do all the work.
- $T_P(n) \ge T_{\infty}(n) \text{ because } P < \infty.$

Therefore

for
$$f(x) \ge C \cdot \max\{a,b\}$$

 $f(n) \in \Omega \left(\max\{a(n),b(n)\}\right)$
 $\Rightarrow f(n) \in \Omega \left(a(n)+b(n)\right)$

$$T_P(n) \in \Omega(\max\{T_1(n)/P, T_\infty(n)\}) = \Omega(T_1(n)/P + T_\infty(n))$$

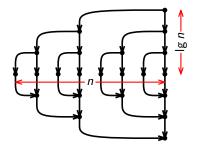

An asymptotically optimal runtime is

$$T_p(n) \in \Theta(T_1(n)/P + T_{\infty}(n)).$$

Good OpenMP implementations guarantee $\Theta(T_1(n)/P + T_\infty(n))$ as their expected runtime.

Runtime of Parallel Divide and Conquer

Work
$$T_1(n) \in \Theta(n)$$
.
Span $T_{\infty}(n) \in \Theta(\log n)$.
So $T_P(n) \in \Theta(n/P + \log n)$.

Since Span $(T_{\infty}(n))$ is so small $(\Theta(\log n))$, our runtime is dominated by n/P for large n.

This means we get linear (in P) speedup over the sequential program, which is the best we could hope for.

```
Runtime of Parallel Count Matches
      omp_set_num_threads(k);
                                       \times) takes time \times
      #pragma omp parallel
         int id=omp_get_thread_num(), lo = id * nn, hi;
         if (id == k-1) hi = n; else hi = lo + nn;
         results[id] = nMatches(A, lo, hi, key);
      }
      int result = 0;
      for( int i = 0; i < k; i++ ) result += results[i];</pre>
      return result;
    Work T_1(n) \in \Theta(n+k) Span T_{\infty}(n) \in \Theta(n/k+k)
   Thus, T_P(n) \in \Theta(\underbrace{n+k}_P) + \underbrace{n/k+k} \subset \Omega(\sqrt{n}).
```

Amdahl's Law

work that must be done sequentially (no other work can be done at the same)

Suppose we know that
$$s$$
 fraction of the Work can't be parallelized. Work that $T_P(n) \geq sT_1(n)/P$ can be done since the best we can hope for is linear speedup on the parallel part.

Amdahl's Law The overall speedup with P processors is:

Speedup
$$\longrightarrow \frac{T_1(n)}{T_P(n)} \leq \frac{1}{s + (1-s)/P}$$
.

The overall speedup with ∞ processors is: $\frac{T_1(n)}{T_{\infty}(n)} \leq \frac{1}{s}$.

Fred Brooks: "Nine women can't make a baby in one month."

Amdahl's Law - Examples

$$\frac{T_1(n)}{T_P(n)} \le \frac{1}{s + (1-s)/P}$$

the max speed processors $\frac{T_1(n)}{T_\infty(n)} \leq \frac{1}{s}$

Suppose s = 33% of a program is sequential.

- ▶ What speedup can you get from 2 processors?
- ▶ What speedup can you get from 1,000,000 processors?
- ▶ Suppose you want 100x speedup with 256 processors?

$$100 \le \frac{1}{s + (1 - s)/256}$$

How small must s be?

$$\frac{S_0 ppose \ s=1/3}{\frac{1}{\frac{1}{\frac{2}{3}} + \frac{2}{3}}} = \frac{3}{2}$$

Prefix Sum

Given an input array, in, of n numbers, produce an output array, out, where $\operatorname{out}[i] = \operatorname{in}[0] + \operatorname{in}[1] + \cdots + \operatorname{in}[i]$.

For example,

```
vector<int> prefixSum(const vector<int>& in) {
  vector<int> out(in.size());
  out[0] = in[0];
  for( int i=1; i<n; ++i )
    out[i] = out[i-1] + in[i];
  return out;
}</pre>
```

n

Map/Reduce? Work $T_1(n) \in \Theta(n)$

Span
$$T_{\infty}(n) \in \Theta(n)$$

Parallel Prefix Sum

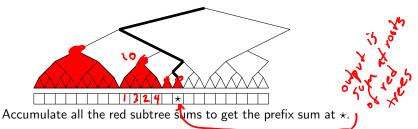

The parallel prefix sum algorithm has two parts:

Part 1 For every subtree of the parallel divide-and-conquer Sum tree, calculate the sums of all leaf entries in the subtree.

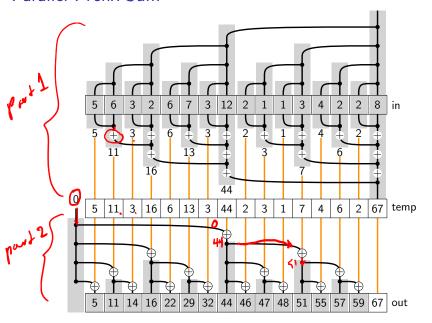

Easy. That's how the Sum tree works.

Part 2 Accumulate the sums from disjoint subtrees to the left of each array position.

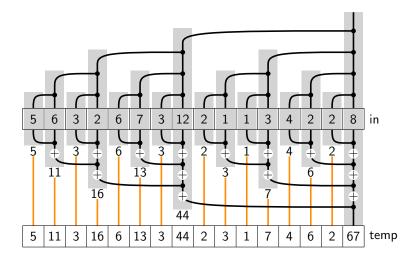

By choosing the biggest subtrees, we accumulate at most $\lg n + 1$ subtree sums for each position.

Parallel Prefix Sum

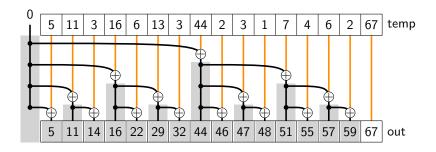

Parallel Prefix Sum Part 1

Work
$$T_1(n) \in \Theta(n)$$

Span
$$T_{\infty}(n) \in \Theta(\log n)$$

Parallel Prefix Sum Part 2

Work
$$T_1(n) \in \Theta(n)$$

Span
$$T_{\infty}(n) \in \Theta(\log n)$$

Pack (a.k.a. Filter) using prefix sum

Given a predicate (boolean function) p and an array in, produce an array out of those in[i] such that p(in[i]) is true, in the same order that they appear in in.

```
\begin{array}{ll} & \text{in} = [17,4,6,8,11,5,13,19,0,24] \\ \text{Example:} & p(x) = (x > 10) \\ & \text{out} = [17,11,13,19,24] \end{array}
```

1. Map to compute bit-vector of true elements.
in [17, 4, 6, 8, 11, 5, 13, 19, 0, 24]
bits [1, 0, 0, 0, 1, 0, 1, 1, 0, 1]

- 2. Prefix Sum on the bit-vector. bitsum [1, 1, 1, 1, 2, 2, 3, 4, 4, 5]
- 3. Map to produce the output.

FORALL(i=0; i \longrightarrow \text{ if (bits[i]) out[bitsum[i]-1] = in[i];} Work
$$T_1(n) \in \Theta(n)$$
 Span $T_{\infty}(n) \in \Theta(\log n)$
