# CPSC 340:
# Machine Learning and Data Mining

Boosting and Start to MLE

# Previously: Ensemble Methods

- Ensemble ~~methods~~ classifiers are classifiers that have classifiers as input.
  - Also called “meta-learning”.
- They have the best names:
  - Averaging.
  - Boosting.
  - Bootstrapping.
  - Bagging.
  - Cascading.
  - Random Forests.
  - Stacking.
- Ensemble methods often have higher accuracy than input classifiers.

# Ensemble Methods

- Remember the fundamental trade-off:
  1. $E_{train}$: How small you can make the training error.

     vs.

  2. $E_{gap}$: how close training error is to test error.
- Goal of ensemble methods is that meta-classifier:
  - Does much better on one of these than individual classifiers.
  - Doesn't do too much worse on the other.
- This suggests two types of ensemble methods:
  1. Averaging: improves generalization gap of classifiers with high $E_{gap}$.
  2. Boosting: improves training error of classifiers with high $E_{train}$.

# AdaBoost: Classic Boosting Algorithm

- A classic boosting algorithm for binary classification is AdaBoost.

- AdaBoost assumes we have a "base" binary classifier that:
  - Is simple enough that it doesn't overfit much.
  - Can obtain >50% weighted accuracy on any dataset.

$$\sum_{i=1}^{n} v_i \mathbb{I}[\hat{y}_i = y_i]$$

$v_i$: weights (sum to 1)

$\mathbb{I}[\hat{y}_i = y_i]$: is example $i$ classified correctly

- Example: decision stumps or low-depth decision trees.
  - Easy to modify stumps/trees to use weighted accuracy as score.

# AdaBoost: Classic Boosting Algorithm

- Overview of AdaBoost:
  1. Fit a classifier on the training data.
  2. Give a higher weight to examples that the classifier got wrong.
  3. Fit a classifier on the weighted training data.
  4. Go back to 2.
     - Weight gets exponentially larger each time you are wrong.

- Final prediction: weighted vote of individual classifier predictions.
  - Trees with higher (weighted) accuracy get higher weight.

- See Wikipedia for precise definitions of weights.
  - Comes from “exponential loss” (a convex approximation to 0-1 loss).

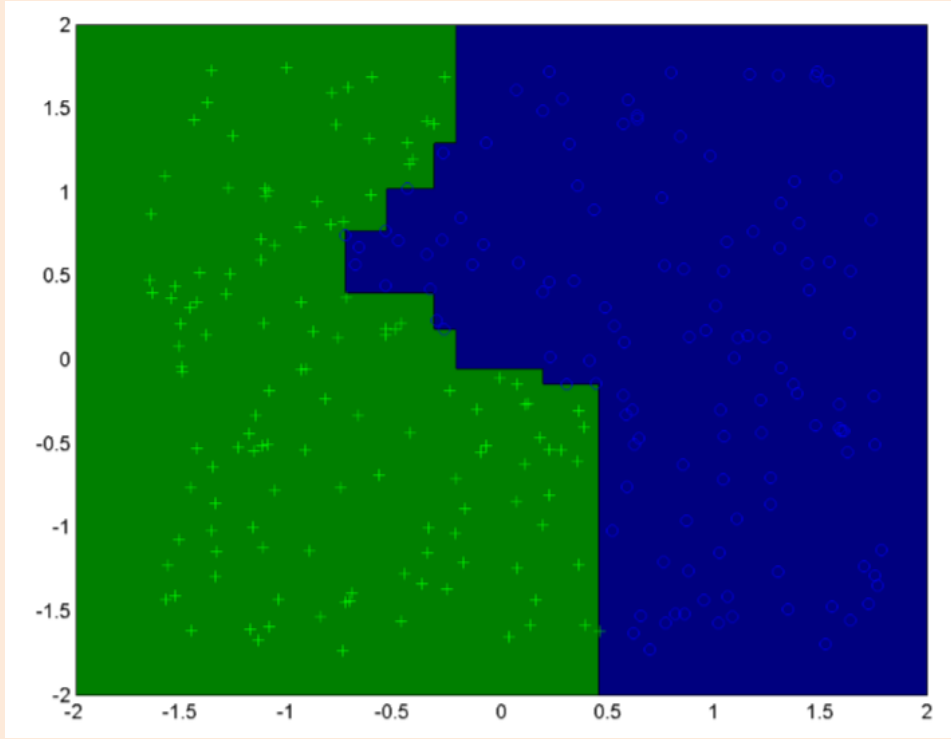
# AdaBoost with Decision Stumps in Action

- 2D example of AdaBoost with decision stumps (with accuracy score):

  - Size of training example on left is proportional to classification weight.

# AdaBoost with Decision Stumps

- 2D example of AdaBoost with decision stumps (with accuracy score):
  - 100% training accuracy.
  - Ensemble of 50 decision stumps.
    - Fit sequentially, not independently.



- Are decision stumps a good base classifier?
  - They tend not to overfit.
  - Easy to get >50% weighted accuracy.

- Base classifiers that don't work:
  - Deep decision trees (no errors to "boost").
  - Decision stumps with infogain (doesn't guarantee >50% weighted accuracy).
  - Weighted logistic regression (doesn't guarantee >50% weighted accuracy).

# AdaBoost Discussion

- AdaBoost with shallow decision trees gives fast/accurate classifiers.
  - Classically viewed as one of the best "off the shelf" classifiers.
  - Procedure originally came from ideas in learning theory.

- Many attempts to extend theory beyond binary case.
  - Led to "gradient boosting", which is like "gradient descent with trees".

- Modern boosting methods:
  - Look like AdaBoost, but don't necessarily have it as a special case.

# XGBoost: Modern Boosting Algorithm

- Boosting has seen a recent resurgence, partially due to XGBoost:
  - A boosting implementation that allows huge datasets.
  - Has been part of many recent winners of Kaggle competitions.

- As base element, XGBoost uses regularized regression trees.

# Regression Trees

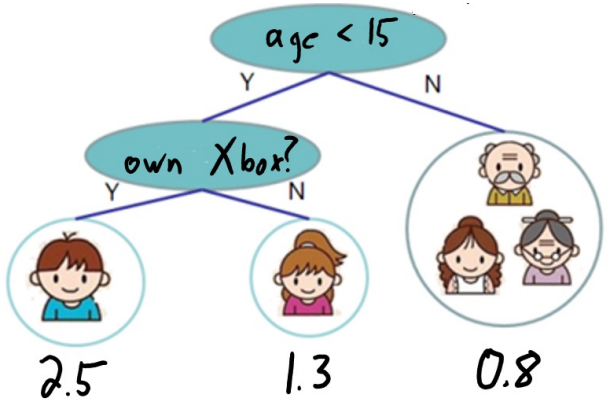
- Regression trees used in XGBoost:
  - Each split is based on 1 feature.
  - Each leaf gives a real-valued prediction.

  - Above, we would predict "2.5 hours" for a 14-year-old who owns an Xbox.

https://xgboost.readthedocs.io/en/latest/tutorials/model.html

# Regression Trees

- How can we fit a regression tree?



- Simple approach:
  - Predict: at each leaf, predict mean of the training $y_i$ assigned to the leaf.
    - Weight $w_L$ at leaf 'L' is set to mean($y_i$) among $y_i$ at the leaf node.
  - Train: set the $w_L$ values by minimizing the squared error,

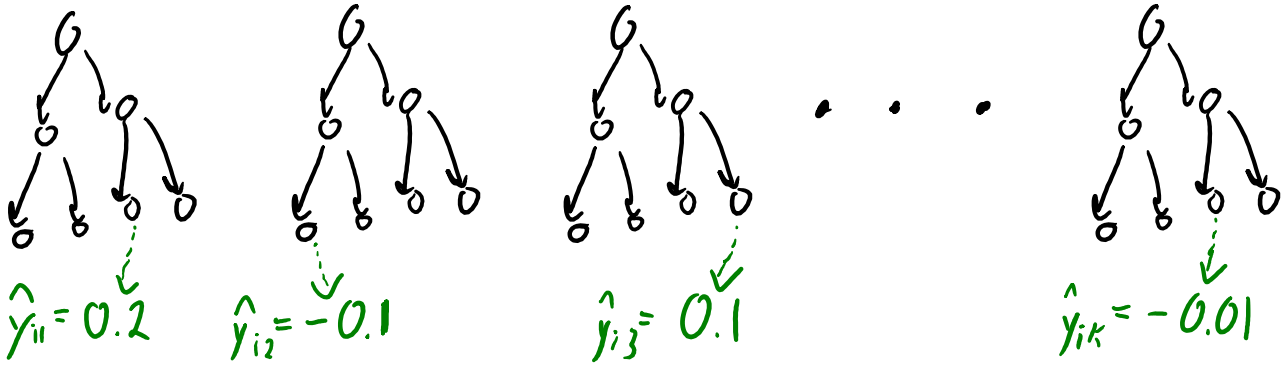
$$f(w_1, w_2, \dots) = \sum_{i=1}^{n} (\underbrace{w_{L_i}}_{\hat{y}_i} - y_i)^2$$

  - Same speed as fitting decision trees from Week 2.
    - Use mean instead of mode, and use squared error instead of accuracy/infogain.
  - Use greedy strategy for growing tree, as in Part 1.

https://xgboost.readthedocs.io/en/latest/tutorials/model.html

# Boosted Regression Trees: Prediction

- Consider an ensemble of regression trees.
  - For an example 'i', they each make a continuous prediction:



- In XGBoost, final prediction is sum of individual predictions:

$$\hat{y}_i = \hat{y}_{i1} + \hat{y}_{i2} + \hat{y}_{i3} + \cdots + \hat{y}_{ik}$$

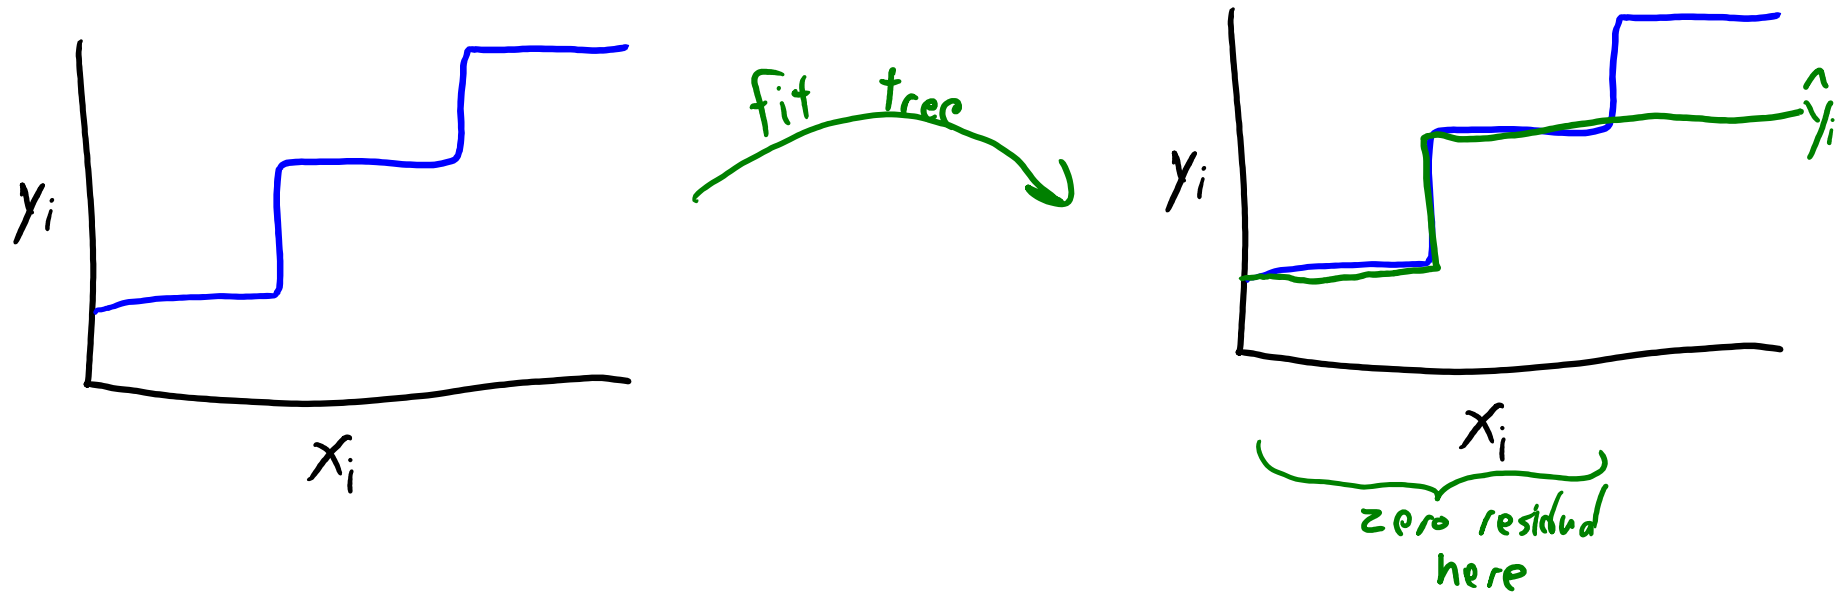
$$= 0.2 + (-0.1) + 0.1 + \cdots + (-0.01)$$

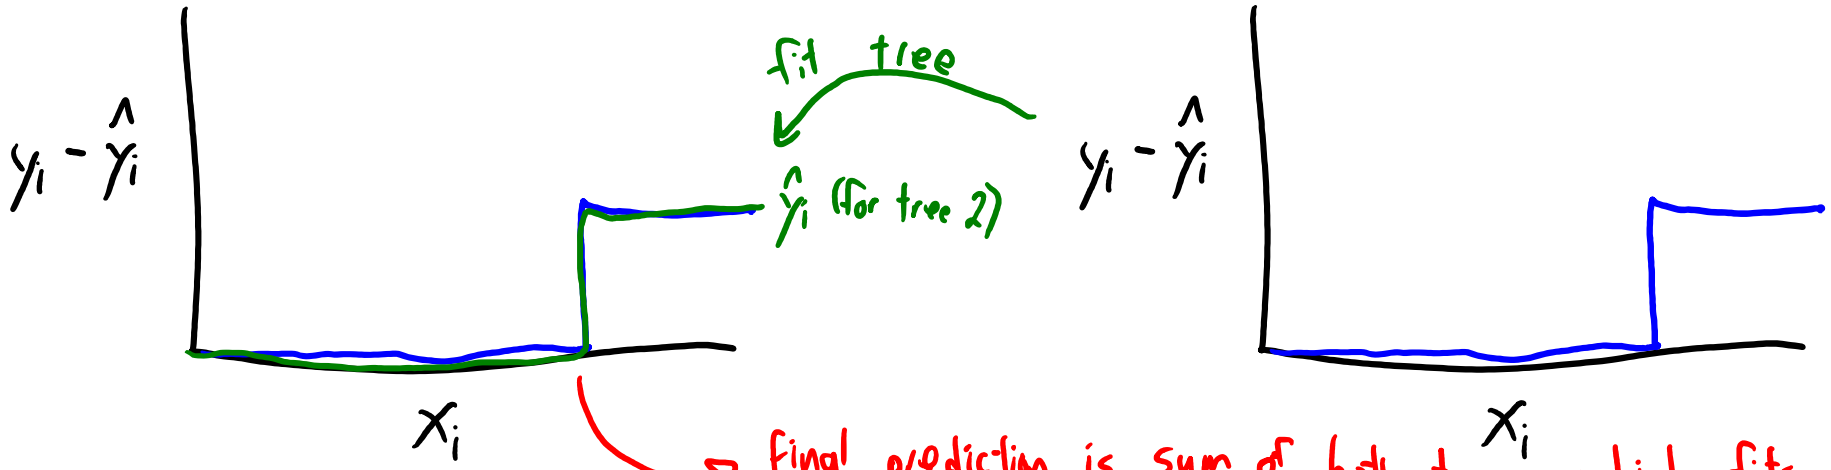
- Notice we aren't using the mean as we would with random forests.
  - In boosting, each tree is not individually trying to predict the true $y_i$ value (we assume they underfit).
  - Instead, each new tree tries to "fix" the prediction made by the old trees, so that sum is $y_i$.

# Boosted Regression Trees: Training

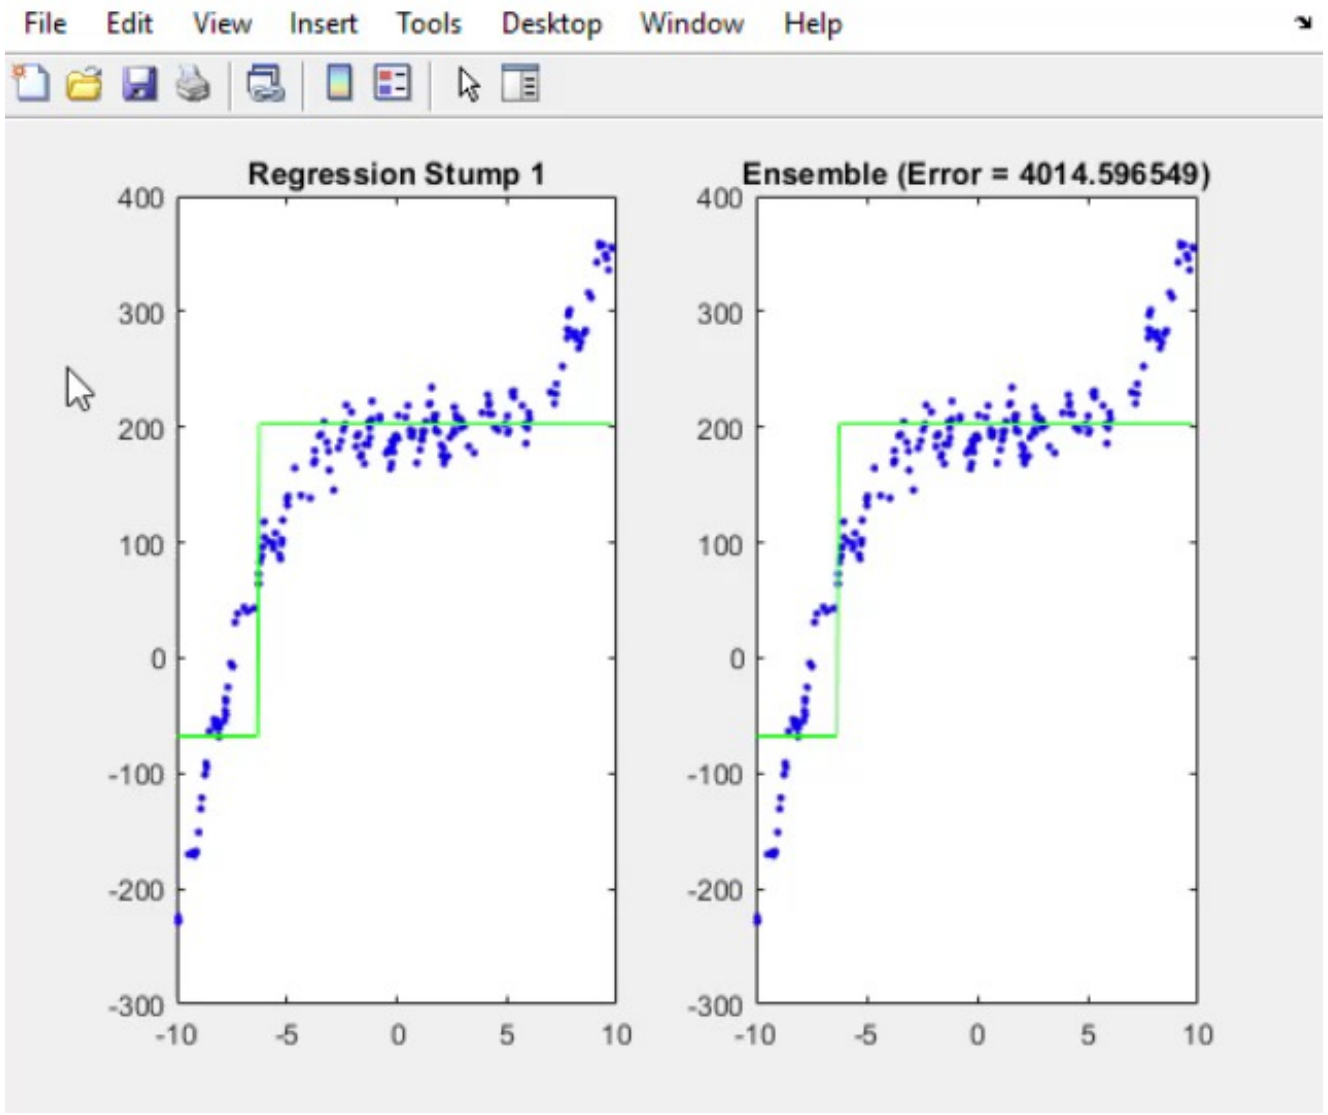
- Consider the following "gradient tree boosting" procedure:
  - Tree[1] = fit(X,y).
  - $\hat{y}$ = Tree[1].predict(X).
  - Tree[2] = fit(X,y - $\hat{y}$).
  - $\hat{y}$ = $\hat{y}$ + Tree[2].predict(X).
  - Tree[3] = fit(X,y - $\hat{y}$).
  - $\hat{y}$ = $\hat{y}$ + Tree[3].predict(X).
  - Tree[4] = fit(X,y - $\hat{y}$).
  - $\hat{y}$ = $\hat{y}$ + Tree[4].predict(X).
  - …
- Each tree is trying to predict residuals ($\hat{y}_i$-$y_i$) of current prediction.
  - "True label is 0.9, old prediction is 0.8, so I can improve $\hat{y}_i$ by predicting 0.1."

# Gradient Tree Boosting in Action





# Gradient Tree Boosting in Action



# Regularized Regression Trees

- Procedure monotonically decreases the training error.
  - As long as not all $w_L=0$, each tree decreases training error.
- It can overfit if trees are too deep or you have too many trees.
  - To restrict depth, add L0-regularization

$$f(w_1, w_2, \dots) = \sum_{i=1}^{n} (w_{L_i} - r_i)^2 + \lambda_0 \|w\|_0$$

    - "Only split if you decrease squared error by $\lambda_0$."
  - To further fight overfitting, XGBoost also adds L2-regularization of 'w'.

$$f(w_1, w_2, \dots) = \sum_{i=1}^{n} (w_{L_i} - r_i)^2 + \lambda_0 \|w\|_0 + \lambda_2 \|w\|^2$$

# XGBoost Discussion

- Instead of pruning trees if score doesn't improve, grows full trees.
  - And then prunes parts that don't improve score with L0-regularizer added.

- Cost of fitting trees in XGBoost is same as usual decision tree cost.
  - XGBoost includes a lot of tricks to make this efficient.
  - But can't be done in parallel like random forest (since fitting sequentially).

- In XGBoost, it's the residuals that act like the "weights" in AdaBoost.
  - Focuses on decreasing error in examples with large residuals.

- How do you maintain efficiency if not using squared error?
  - For non-quadratic losses like logistic, there is no closed-form solution.
  - Approximates non-quadratic losses with second-order Taylor expansion.
    - Maintains least squares efficiency for other losses (by approximating with quadratic).

# Next Topic: Maximum Likelihood Estimation

# Motivation for Learning about MLE and MAP

- Next topic: maximum likelihood estimation (MLE) and MAP estimation.
  - Crucial to understanding advanced methods, notation can be difficult at first.

- Why are we learning about these?
  - Justifies the naïve Bayes "counting" estimates for probabilities.
  - Shows the connection between least squares and the normal distribution.
  - Makes connection between "robust regression" and "heavy tailed" probabilities.
  - Shows that regularization and Laplace smoothing are doing the same thing.
  - Justifies using sigmoid function to get probabilities in logistic regression.
  - Gives a way to write complicated ML problems as optimization problems.
    - How do you define a loss for "number of Facebook likes" or "1-5 star rating"?
  - Crucial to understanding advanced methods.

# But first: "argmin" and "argmax"

- We've repeatedly used the min and max functions:

$$\min_w\{w^2\}=0 \qquad \max_w\{\cos(w)\}=1$$

  - Minimum (or maximum) value achieved by a function.

- A related set of functions are the argmin and argmax:
  - The set of parameter values achieving the minimum (or maximum).

$$\min_w\{(w-1)^2\}=0$$

$$\operatorname{argmin}_w\{(w-1)^2\}=1$$

'1' is the 'w' value that gives the min.

$$\operatorname{argmin}_w\left\{\frac{1}{2}\|Xw-y\|^2+\frac{\lambda}{2}\|w\|^2\right\}=(X^TX+\lambda I)^{-1}(X^Ty)$$

$$\operatorname{argmax}_w\{\cos(w)\}=0,\ 2\pi,\ 4\pi,\ldots$$

# But first: “argmin” and “argmax”

- The last slide is a little sloppy for the following reason:
  - There may be multiple values achieving the min and/or max.
  - So the argmin and argmax return sets.

$$\operatorname{argmin}_w \{(w-1)^2\} \equiv \{1\}$$

"set containing the element '1'"

"sets are equivalent"

$$\operatorname{argmax}_w \{\cos(w)\} \equiv \{\ldots, -4\pi, -2\pi, 0, 2\pi, 4\pi, \ldots\}$$

$$\operatorname{argmin}_w \left\{\frac{1}{2}\|Xw-y\|^2\right\} \equiv \{w \mid X^TXw = X^Ty\}$$

  - And we don’t say a variable “is” the argmax, but that it “is in” the argmax.

$$2\pi \in \operatorname{argmax}_w \{\cos(w)\} \qquad (X^TX+\lambda I)^{-1}(X^Ty) \in \operatorname{argmin}_w \left\{\frac{1}{2}\|Xw-y\|^2 + \frac{\lambda}{2}\|w\|^2\right\}$$

# The Likelihood Function

- Suppose we have a dataset ‘D’ with parameters ‘w’.

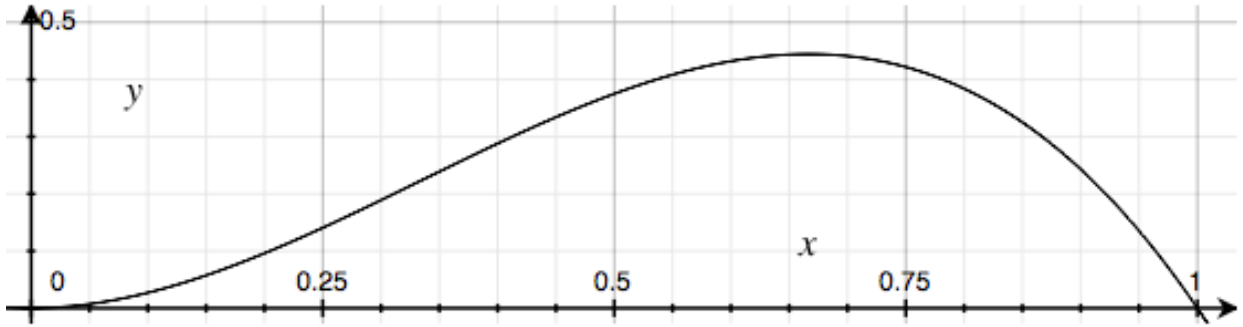
- For example:
  - We flip a coin three times and obtain D={“heads”, “heads”, “tails”}.
  - The parameter ‘w’ is the probability that this coin lands “heads”.

- We define the likelihood as a probability mass function $p(D \mid w)$.
  - “Probability of seeing this data, given the parameters”.
  - If ‘D’ is continuous it would be a probability “density” function.

- If this is a “fair” coin (meaning it lands “heads” with probability 0.5):
  - The likelihood is $p(HHT \mid w=0.5) = (1/2)(1/2)(1/2) = 0.125$.
  - If $w = 0$ (“always lands tails”), then $p(HHT \mid w = 0) = 0$ (data is less likely for this ‘w’).
  - If $w = 0.75$, then $p(HHT \mid w = 0.75) = (3/4)(3/4)(1/4) \approx 0.14$ (data is more likely).

# Maximum Likelihood Estimation (MLE)

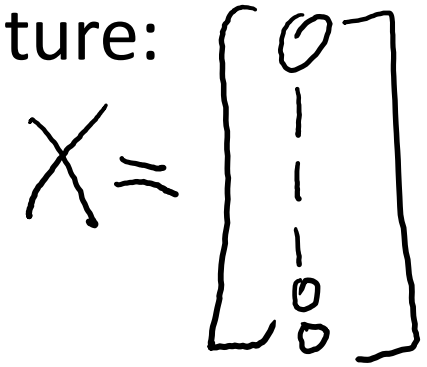
- We can plot the likelihood p(HHT | w) as a function of 'w':



- Notice:
  - Data has probability 0 if w=0 or w=1 (since we have 'H' and 'T' in data).
  - Data doesn't have highest probability at 0.5 (we have more 'H' than 'T').
  - This is a probability distribution over 'D', not 'w' (area isn't 1).
- Maximum likelihood estimation (MLE):
  - Choose parameters that maximize the likelihood: $\hat{w} \in \arg\max_w \{p(D|w)\}$
    - In this example, MLE is 2/3.

# MLE for Binary Variables (General Case)

- Consider a binary feature:



- Using 'w' as "probability of 1", the maximum likelihood estimate is:

$$\hat{w} = \frac{\#\text{ of ones}}{\#\text{ of examples}}$$

- This is the "estimate" for the probabilities we used in naïve Bayes.
  - The conditional probabilities we used in naïve Bayes are also MLEs.
    - The derivation is tedious, but if you're interested I put it here.

# Next Topic: Least Squares and MLE

# Maximum Likelihood Estimation (MLE)

- Maximum likelihood estimation (MLE) for fitting probabilistic models.
  - We have a dataset D.
  - We want to pick parameters 'w'.
  - We define the likelihood as a probability mass/density function p(D | w).
  - We choose the model $\hat{w}$ that maximizes the likelihood:

$$\hat{w} \in \underset{w}{\operatorname{argmax}} \{ p(D|w) \}$$

- Appealing "consistency" properties as n goes to infinity (take STAT 4XX).
  - "This is a reasonable thing to do for large data sets".

# Least Squares is Gaussian MLE

- It turns out that most objectives have an MLE interpretation:
  - For example, consider minimizing the squared error:

$$f(w) = \frac{1}{2}\|Xw - y\|^2$$

  - This gives MLE of a linear model with IID noise from a normal distribution:

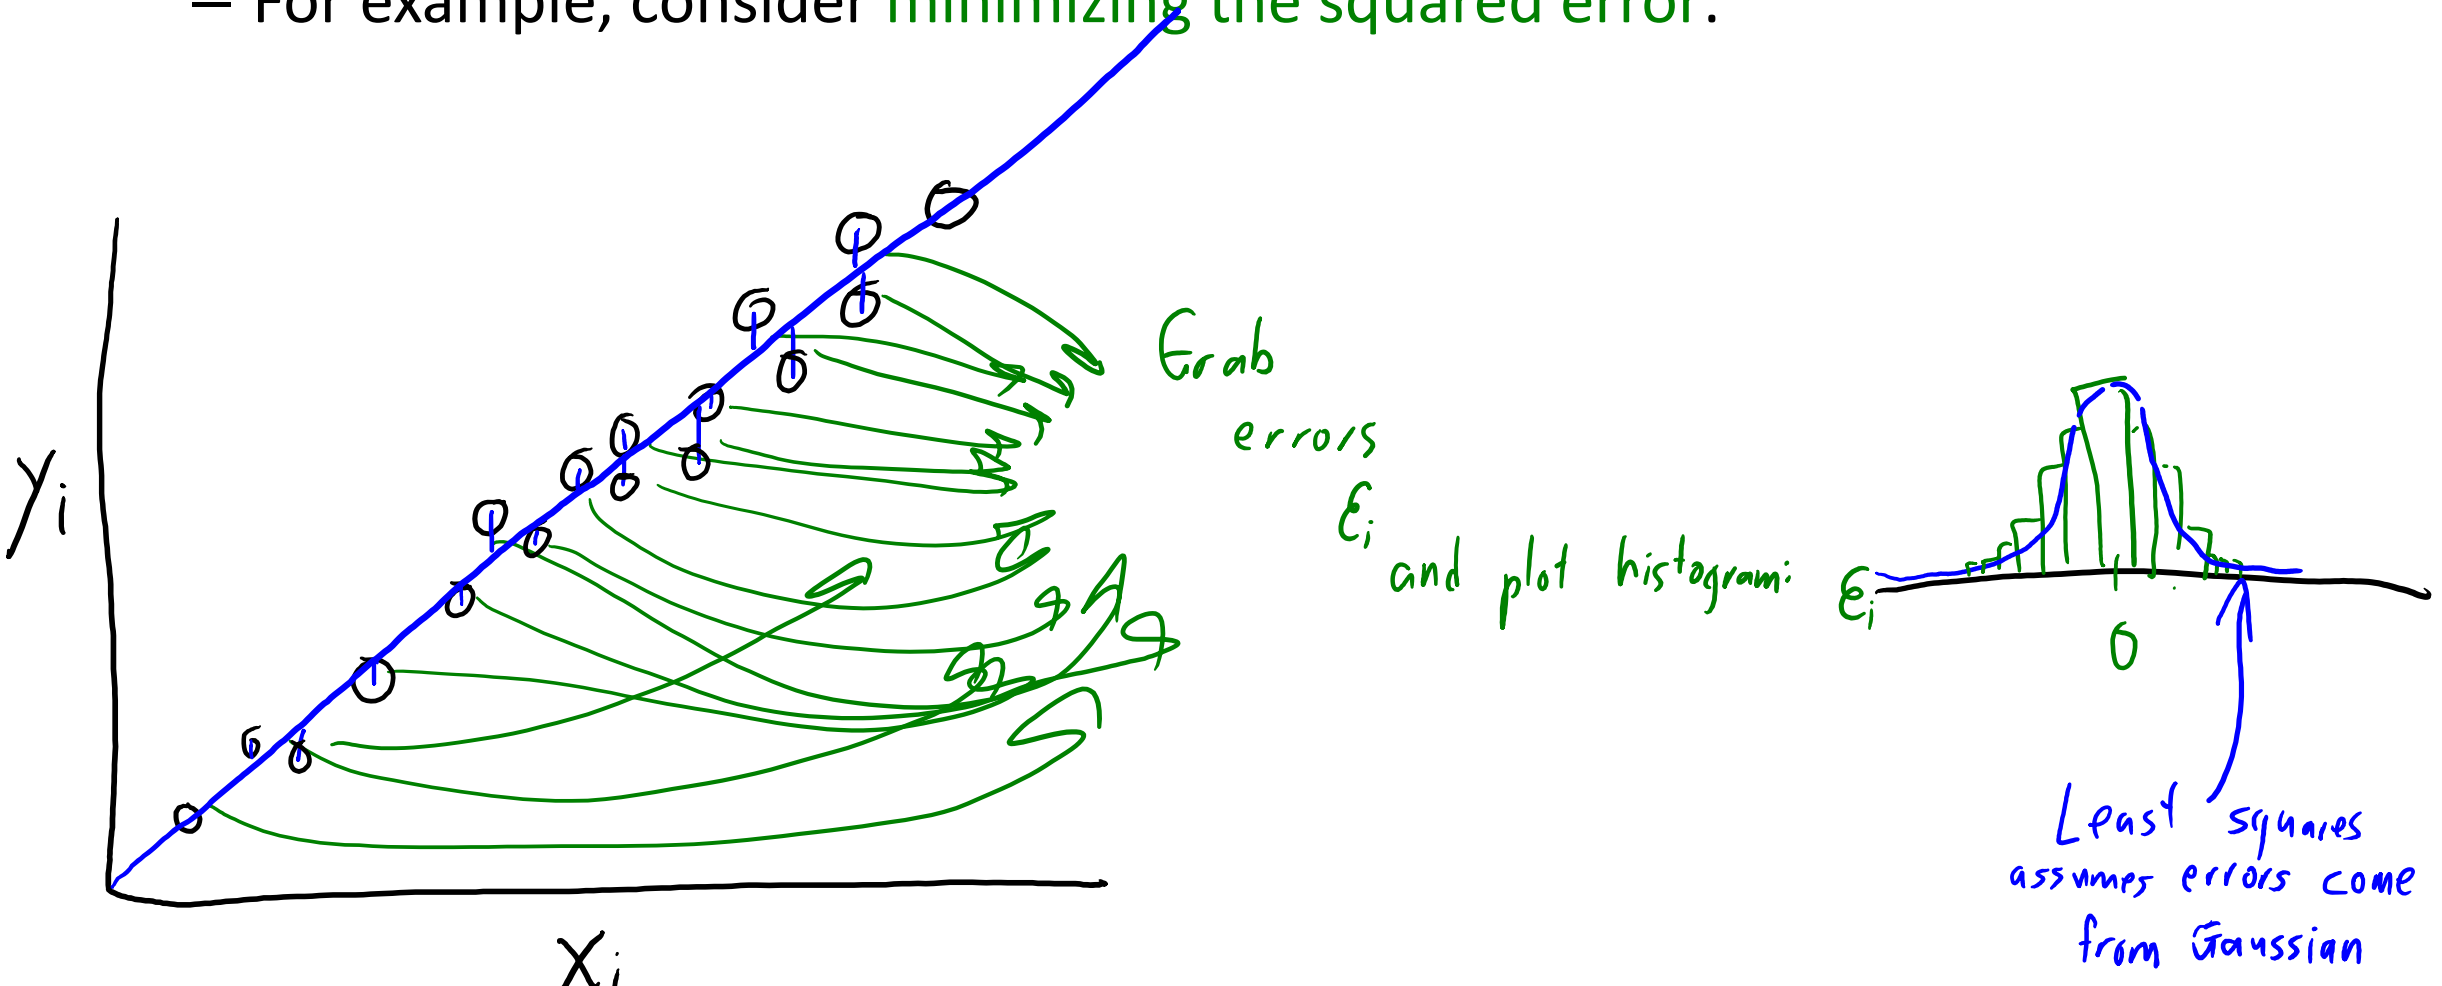
$$y_i = w^T x_i + \varepsilon_i$$

where each $\varepsilon_i$ is sampled independently from standard normal

    - "Gaussian" is another name for the "normal" distribution.
  - Remember that least squares solution is called the "normal equations".

# Least Squares is Gaussian MLE

- It turns out that most objectives have an MLE interpretation:
  - For example, consider minimizing the squared error:



# Minimizing the Negative Log-Likelihood (NLL)

- To compute maximize likelihood estimate (MLE), usually we equivalently minimize the negative "log-likelihood" (NLL):
  - "Log-likelihood" is short for "logarithm of the likelihood".

$$\hat{w} \in \operatorname*{argmax}_w \{p(D|w)\} \equiv \operatorname*{argmin}_w \{-\log(p(D|w))\}$$

"equivalent"

- Why are these equivalent?
  - Logarithm is strictly monotonic: if $\alpha > \beta$, then $\log(\alpha) > \log(\beta)$.
    - So location of maximum doesn't change if we take logarithm.
  - Changing sign flips max to min.

- See Max and Argmax notes if this seems strange.

# Summary

- Boosting: ensemble methods that improve training error.
- XGBoost: modern boosting method based on regression trees.
  - Each tree modifies the prediction made by the previous trees.
  - L0- and L2-regularization used to reduce overfitting.
- Maximum likelihood estimate:
  - Maximizing likelihood p(D | w) of data ‘D’ given parameters ‘w’.

- Next time:
  - How does regularization and Laplace smoothing fit it?
